Abstract

There has recently been an interest in Reconfigurable Mesh (RM) because of its simplicity and dynamic nature. Among many applications, RM can be viewed as a part of a powerful image understanding architecture for supporting real time image understanding applications. This paper defines a programming model for the general RM which is expressed by means of a programming language, called RPC (Reconfigurable Parallel C). The paper also presents a serial simulator, RMSIM (Reconfigurable Mesh SIMulator), which permits to study RPC programs written for a subnetwork of 3-D RM, known as mesh of meshes, where buses can be formed only in 2-D space. RMSIM is an easy-to-use simulator capable of simulating any RPC program in different axis-orientations within restricted regions. To enhance the debugging facilities, RMSIM is equipped with a snapshotter to generate BTEX pictures of any planar segment of the simulated mesh at any step of program execution.

Keywords: Reconfigurable mesh; Image processing; Simulation; Parallel programming; Programming language

1 Introduction

It is well-known that interprocessor communications and simultaneous memory accesses often act as bottlenecks in present-day parallel machines. Bus systems have been introduced recently to a number of parallel machines to address this problem. Examples include the Bus Automaton [17], the Reconfigurable Mesh (RM) [14, 20], the Content Addressable Array Parallel Processor (CAAPP) [22], and the Polymorphic Torus [12]. A bus system is called reconfigurable if it can be dynamically changed according to either global or local information.

Among many applications, RM can be viewed as a part of a powerful image understanding architecture for supporting real-time image understanding applications and research in knowledge-based computer vision [22]. Recently, constant time algorithms have been developed on RM for a number of image processing problems [4, 6, 7, 8, 14, 15].

Research on reconfigurable mesh has concentrated mainly on the development of computation models and on the implementation of experimental systems. The experimental systems YUPEP [10, 11] and GCN [18] have mainly focused on the efficient implementation of the hardware supporting reconfigurability, and have not produced any programming model.

The lack of a programming model, in particular, makes the development of RM algorithms very difficult; the algorithms are usually formulated as sequences of steps involving the manipulation of switches that control reconfiguration and neither automatic validation nor simulation can be done. On the contrary, a programming model supporting a high level language and a simulator would allow for the automatic validation of the algorithms and for the automatic performance evaluation of the programs.

Maresca [12] has expressed his concern that the general RM is so flexible and powerful that it has turned out to be impossible to derive high level programming models preserving such flexibility and power. Maresca, therefore, has pruned the flexibility and power of the general RM in defining a new reconfigurable mesh architecture, Polymorphic Processor Arrays (PPA), for which a programming model has been proposed as a basis for the design of a parallel programming language, called PPC (Polymorphic

Parallel C), and a compiler/simulator has been implemented [12].

PPC is a well defined programming model but it addresses only the issues concerning PPA. Recently, Ben-Asher et al. [1, 2, 3] have proposed a systematic approach in expressing RM algorithms where each step of an algorithm is divided into four substeps in sequence as discussed in Section 2. This has motivated us to define a programming model of the general RM and to write a serial simulator, RMSIM (Reconfigurable Mesh SIMulator) to support the model. The RM programming model is expressed by means of a programming language, called RPC (Reconfigurable Parallel C). RMSIM, written in ANSI C, can simulate a subnetwork of a 3-dimensional reconfigurable mesh known as mesh of meshes (Section 2). This simulator has an in-built interpreter to execute RPC programs. The interpreter is capable of executing a program in different axis-orientations within restricted regions. In defining RPC, we have concentrated on making the effort of transforming the algorithms into equivalent programs straightforward and easy. To aid in debugging, RMSIM is capable of generating PostScript picture of any planar segment of the mesh, at any step, while executing a program.

This paper is organized as follows. In the next section we present the computational model of RM. Section 3 defines a programming model for RM. Issues of serial accessing of processing elements are addressed in Section 4. In Section 5 we briefly describe the debugging facilities of RMSIM. Section 6 concludes the paper.

## 2 RM Computational Model

The Reconfigurable MESH (RMESH) [14] and the Processor Array with a Reconfigurable Bus System (PARBS) [20] gained wide acceptance in the literature as RM computational models. Li and Stout [9] have demonstrated that PARBS is probably more powerful than RMESH by showing the performance difference of the computation of exclusive-or (XOR) on PARBS and RMESH models. We, therefore, consider PARBS to be the RM computational model in the rest of this paper.

The reconfigurable mesh is primarily a two-dimensional mesh of processors connected by reconfigurable buses. In this parallel architecture, a processor element (PE) is placed at the grid points as in the usual mesh connected computers. Each PE is connected to at most four neighbouring PEs through fixed bus segments connected to four I/O ports E & W along dimension x and N & S along dimension y. These fixed bus segments are the building blocks of larger bus components which are formed through switching, decided entirely on local data, of the internal connectors (see Figure 2) between the I/O ports of each PE. The possible fifteen interconnections of I/O ports through switching are shown in Figure 2. The connection patterns are represented as \( \{p_1, p_2, \ldots\} \), where each of \( p_i \) represents a group of switches connected together such that \( \bigcup_{i \in \mathbb{N}} p_i = \{N, E, W, S\} \). For example, \( \{NS, E, W\} \) represents the connection pattern with ports N and S connected and ports E and W unconnected. Like all bus systems, the behaviour of RM relies on the assumption that the transmission time of a message along a bus is independent of the length of the bus [3].

![Figure 2: Possible fifteen internal connections between the four I/O ports of a PE.](image)

A reconfigurable mesh operates in the single-instruction multiple-data (SIMD) mode. Besides the reconfigurable switches, each PE has a computing unit with a fixed number of local registers. A single time step of an RM is composed of the following four substeps:

**BUS substep.** Every PE switches the internal connectors between I/O ports by local decision.

**WRITE substep.** Along each bus, one or more PEs on the bus transmit a message of length bounded by the bandwidth of the fixed bus segments as well as the switches. These PEs are called the *speakers*. A bus is called to be in *ambiguous* state when there are more than one speakers. In the most common *exclusive write* model, the ambiguous state is considered to be an *error* state. The *common write* model [15, 4] allows multiple processors broadcasting simultaneously to the same bus so long as they all
broadcast the same message. Otherwise, the ambiguous state is considered to be an error state. In both the models it is assumed that the error state is detectable by the processors and the bus carries arbitrary value. The most powerful concurrent write model [23] also allows multiple processors broadcasting simultaneously to the same bus and the bus always carries the wired-or of all the messages.

**READ substep.** Some or all the PEs connected to a bus read the message transmitted through.

**COMPUTE substep.** A constant-time local computation is done by each PE.

Reconfigurable meshes of higher dimension can be constructed in a similar way. A number of interesting algorithms [3, 5, 13, 19, 21] have appeared in the literature for multi-dimensional RMs. In most of the cases [3, 5, 13, 21], 3-D RM with two additional ports U and D along dimension z was considered because of a subnetwork of it, known as mesh of meshes, where buses can be formed only in 2-D space. In a mesh of meshes, not all the six ports, N, S, E, W, U, D, can participate simultaneously in configuring dynamic interconnections. Only the ports on the same plane can be interconnected and all the possible 15 interconnections among each set of ports \{E, W, N, S\} on XY-plane, \{E, W, U, D\} on XZ-plane, and \{N, S, U, D\} on YZ-plane are allowed. To overcome the implementation issues, optimal simulation of higher dimensional RMs by 2-D ones is addressed in [19].

### 3 RM Programming Model

RMC is an extension of ANCI C. In fact, RM-SIM is implemented as an ANCI C library preserving Object Oriented Programming (OOP) principles through data hiding. Like C, RPC is designed to be small. RPC programs, therefore, are assumed to be dependent extensively on library programs which are not the integral part of the core of the language.

#### 3.1 Initialisation and Basic Assumptions

Initialisation of the RM system to be simulated is carried out by calling the function SetGlobalDim() in the main(). SetGlobalDim() sets size \(N_x \times N_y \times N_z\) of the simulated RM, regN number of registers per PE, and bus write mode (exclusive|common|Concurrent).

To locate a PE into the simulated mesh of meshes, 3-D Cartesian coordinates are used. Let \(PE_{x,y,z}\) denote the PE at the coordinate \((x,y,z)\). In every RPC program, the \(XY-Z\) axis-orientation is assumed to be the base plane while the others planes are supporting planes. Let this axis-orientation be called \(XY-Z\) as shown in Figure 3. Possible five other axis-orientations \(YZ-X, ZY-X, ZX-Y, YZ-X\), and \(XZ-Y\) play important role in program reusability as discussed in Section 3.3.

An RPC program also assumes that it will be executed in a restricted region of the simulated mesh defined by the constants \(S_x, S_y, S_z, E_x, E_y, E_z\), which includes only the processing elements \(PE_{x,y,z}\), \(\min(S_x,E_x) \leq x \leq \max(S_x,E_x), \min(S_y,E_y) \leq y \leq \max(S_y,E_y), \min(S_z,E_z) \leq z \leq \max(S_z,E_z)\). This assumption also helps in program reusability which is discussed in Section 3.3.

::ProgramName
S:: Start of Program Statement;
G:: begin of Every Step Statement;
B:: Bus Statement;
W:: Write Statement;
R:: Read Statement;
C:: Compute Statement;
F:: finish of Every Step Statement;
::
E:: End of Program Statement;

Figure 4: RPC program layout in execution sequence.

#### 3.2 Program Layout

The layout of an RPC program is given in Figure 4. This layout also shows the sequence of execution. The S::, G::, C::, F::, and E:: statements are optional. Every B:: statement starts a step and the G::(F::) statement is executed at the beginning(end) of each step. The statements can be simple or complex. As in C, a complex statement is recursively defined as a sequence of simple or complex statements enclosed in curly braces.

#### 3.3 Data Structure

RPC assumes data width of the simulated mesh to be the sizeof(double). The registers are consid-
ered as double variables and the bandwidth of the buses and ports are assumed to be the data width. It is programmer’s responsibility to interpret the content of a register otherwise, if other simple data types e.g. int, char, etc. are to be used. In a similar way complex data types can also be handled. Registers are indexed from 0 to regN - 1. To enforce data hiding, registers are accessed only through the following two functions:

- SetReg(reg, val) – sets the content of register reg with val.
- GetReg(reg, val) – gets the content of register reg.

### 3.4 Data Communication

Data communication in RPC is supported by four primitives, available in the form of the following functions:

- Bus(set_1, set_2, ...) – selects the connection pattern {set_1, set_2, ...} as the interconnection of I/O ports. There can at most be six parameters and each parameter is a string of characters drawn from the alphabet {E, W, N, S, U, D} such that ∪v_i set_i = {E, W, N, S, U, D} and ∀i : ∀j ≠ i : set_i ∩ set_j = {}. As RMSIM simulates only a mesh of meshes, it carries no meaning if a parameter contains characters from all the three sets {E, W}, {N, S}, and {U, D}.
- Write(prt, val) – writes the val on the bus connected to the port prt.
- Read(prt) – reads the content of the bus connected to the port prt.
- Error(prt) – returns 1 if the bus connected to the port prt is in error state; returns 0 otherwise.

### 3.5 Program Reusability

Like many other programming languages, RPC is capable of using previously written programs into a new program through subroutine calls. Many RM algorithms appeared in the literature containing references to other published algorithms. This simplified the description of those algorithms significantly. The capability of reusing programs enables a programmer to convert those algorithms into programs in similar straightforward fashion.

Program reusability in RPC is supported by the function Call(Program_Name, Requested_Axis_orientation, sx, ex, sy, ey, sz, ez). Reusability of program through this function depends on the following key issues:

**Call Stack** – It is assumed that each PE is equipped with an internal stack to preserve the values of Sx, Sy, Sz, Ex, Ey, Ez when a subroutine call is made to another program.

**Figure 5:** Possible six axis-orientations.

**Axis-orientation Mapping** – It has already been mentioned in Section 3.1 that while a program is written, RPC assumes XY, Z to be the axis-orientation. But during a subroutine call a program can be executed in any of the possible six axis-orientations as shown in Figure 5. RPC allows nesting of subroutine calls and the axis-orientation is selected accordingly. Suppose the current axis-orientation and the Requested_Axis_orientation be YZ, X, XY, YZ, RPC will then select YX, Z as the resultant axis-orientation.

The example RPC program (Figure 6) of computing the ranks of N distinct numbers on an N × N × N mesh of meshes exemplifies the axis-orientation mapping. Let the number n_i be stored in PE_{i,0,0}, 0 ≤ i < N. Now a row broadcast after a column broadcast is done to distribute the numbers in the XY-plane so that PE_{i,j,0}, 0 ≤ i, j < N, receives the pair (n_i, n_j) and then produces 1, if n_i > n_j, or 0, otherwise. Ranks are now computed by simply calling the program PrefixSum in XYZ axis-orientation in every YZ-plane to add the comparison values along each column.

**Region Mapping** – Enhancement in the power of program reusability through axis-orientation mapping cannot be realised completely if no way is allowed to call a program in a restricted area of the mesh of meshes e.g. in the previous example of computing ranks each call of the program PrefixSum uses a specific YZ-plane rather than using the entire mesh of meshes. RPC assumes that a program will be executed in a restricted region of the mesh of meshes defined by the constants Sx, Sy, Sz, Ex, Ey, Ez as mentioned in Section 3.1. Hence, defining a restricted region in program Calling is as simple as assigning Sx = sx, Ex = ex, and so on.
Figure 7: A restricted region in a $5 \times 5 \times 5$ mesh of meshes.

for $z = 2$ to 3 step 1
for $y = 1$ to 3 step 1
for $x = 4$ to 1 step -1

5 Debugging in RMSIM

RMSIM generates run time error codes while interpreting a program if problem occurs. Besides this standard technique, RMSIM is also equipped with a snapshotter which can be used to generate \LaTeX picture of the bus configurations, along any plane of the simulated mesh of meshes, at any step of program execution. The generated pictures are scalable and can show the content of the registers of each PE.

6 Conclusion

This paper defines a programming model for the general RM which is expressed by means of a programming language, called RPC (Reconfigurable Parallel C). The paper also presents a serial simulator, RMSIM (Reconfigurable Mesh SIMulator), which can simulate a subnetwork of 3-D RM known as mesh of meshes. Besides simulating, RMSIM provides a program interpreter which can execute RPC programs in any possible axis-orientation within an enclosed region. RMSIM can generate snapshots of any planar segment of the simulated mesh in \LaTeX picture format.
